Improving OCC Performance Through Transaction Batching and Operation Reordering

ABSTRACT

OLTP systems can often improve throughput by *batching* transactions and processing them as a group. This batching has been used for optimizations such as message packing and group commits; however, there is little research on the benefits of a holistic approach to batching across a transaction's entire life cycle.

In this paper, we present an OLTP system based on optimistic concurrency control that incorporates batching at multiple stages of transaction execution. Batching enables reordering operations to improve performance and reduce conflicts: Storage batching enables reordering of transaction reads and writes at the storage layer, and validator batching enables reordering of transactions before validation. We formalize the problem of validator transaction reordering, and we propose several algorithms and policies customizing for various goals. We further explain how to parallelize validation for better performance. We carry out an in-depth experimental evaluation of the impact of storage and validator batching, and we show that our techniques can significantly increase throughput and reduce latency. We show how different batching algorithms perform, how parallelism in validator reordering helps, how storage and validator batching interact with each other, and how they improve system-wide and individual transaction performance.

1 INTRODUCTION

Transaction processing is a fundamental aspect of database functionality, and improving OLTP system performance has long been a key research goal in our community. It is well-known that the throughput of OLTP systems can be increased through *batching*-based optimizations, whereby some component buffers a number of transactions or requests as they arrive and processes them as a group.

Batching can improve system performance for several reasons. First, it increases the efficiency of communication by packing messages [15, 22]. Second, it amortizes the cost of system calls by condensing multiple requests into a single one, as in group commit [14, 25]. Third, it reduces the number of requests by discarding duplicate or stale requests, such as writes to the same record [19]. However, all of those are local optimizations based on low-level techniques.

We propose an OLTP system design that embraces batching as a core design principle throughout transaction execution. In particular, we explore the benefits of incorporating reordering into batching in optimistic concurrency control (OCC) to reduce conflicts [33]. OCC is a popular concurrency control protocol due to its low overhead in low-contention settings [2, 5, 7–9, 12, 17, 35, 40, 42]. However, it wastes resources when conflicts are frequent [3]. We show batching and reordering reduce the number of conflicts, improve throughput and latency, and allow us to use OCC with higher-contention workloads.

Figure 1 shows a loosely coupled OCC-based transaction processing system with centralized validation. The system consists of three components: the processor, the storage, and the validator. External clients issue transactions to the system. On arrival into the system, each transaction is assigned to a processor and enters its *read* phase. The processor sends read requests to the storage, executes the transaction, and performs writes to a local workspace. After it has processed the transaction, it sends information about the transaction's reads and writes to the validator.

The transaction now enters the *validation* phase. In OCC with *backward validation*, the validator checks if a particular transaction conflicts with any previously committed ones. One example of a conflict that would fail validation is a *stale read*. Suppose a transaction t reads an object x, and a second transaction t' writes to the same object after t's read. If t' commits before t, t has a conflict, since it should have read the update t' made to x. Hence, t must fail validation.

If a transaction passes validation, the processor sends its writes to the storage; this is the *write* phase. Otherwise, the processor aborts and restarts the transaction.

The architecture of OCC with backward validation presents unique opportunities for batching because transactions are only serialized prior to commit. There are three obvious places to apply batching. The first is the processor in the transactions' read phase, where transaction requests can be batched before execution. Recent works in the context of locking-based protocols batch transactions and serialize them before execution to reduce overhead [18, 38, 47]; these techniques could be adapted and applied in OCC as well.

The second possible place is the validator. If the validator buffers the requests, it can choose a validation order that reduces the number of conflicts and aborts. In our previous example, t reads the object x, and t' writes to x after t's read. Without batching, if t' arrives at the validator before t and commits, t will fail. With batching, we can serialize t before t' if they are in the same validation batch, and commit both transactions without any aborts.

Third, batching can be done at the storage level. This affects already-validated transactions in their write phase as well as transactions still in their read phase. The storage can buffer read and

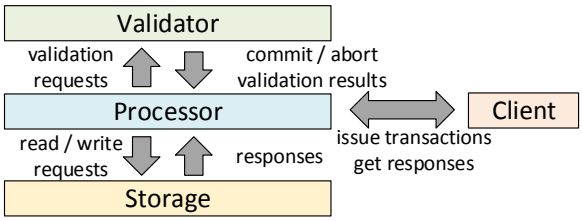

Figure 1: OCC system architecture

write requests into batches as they arrive. If a batch contains multiple read and write requests for the same object, the system can apply all the writes first, in the serialization order. Next, it can process the reads. Prioritizing writes over reads is always optimal as this reduces the number of aborts later in the validator as much as possible. This is because OCC reads come from uncommitted transactions, while writes come from validated transactions that will commit soon. Thus, if the storage schedules a pending read before a pending write on the same object, the reading transaction will see a stale value and is guaranteed to fail validation.

Contributions. In this paper, we explore in-depth the benefits of transaction batching and operation reordering in OCC with backward validation, with a focus on storage and validator batching. Our system design is best suited for integration with an in-memory versioned key-value store, as we require the ability to customize the validation logic. Previous work on the Centiman system[15] proposed a loosely coupled architecture for OCC on top of key-value stores. The system we present here follows Centiman's architecture and enhances its design with batching and reordering.

Our first contribution is an enhanced OCC system architecture that utilizes batching and reordering at the storage and the validator levels. We analyze the reasons for conflicts and aborts at each stage of a transaction's life cycle, and develop techniques to reduce these aborts through batching.

Our second contribution is an optimal algorithm for storage reordering and approximate algorithms for validator reordering. We show that finding the optimal transaction ordering within a validator batch is NP-hard. We then describe two classes of greedy algorithms that balance abort rates and reordering overheads. These algorithms produce transaction orderings that are close to the optimal solution, and are sufficiently fast for practical use. We also extend these algorithms to weighted versions that can incorporate features such as transaction priorities.

Our third contribution is a design that reduces the amortized overhead of validation through parallelism. The parallelization is achieved with a three-stage pipeline, where the stages are batch preparation, transaction reordering, and transaction validation. Each of these stages can be further parallelized to allow concurrent processing.

Our final contribution is a detailed experimental study of the impact of storage and validator batching in a prototype system, as well as a client side implementation on a commercial database system. Our results show that batching and reordering always increases transaction throughput and, surprisingly, also reduces transaction latency, especially the tail latency. For workloads with high data contention, batching and reordering can improve the throughput by up to a factor of 3.1x and can reduce the average transaction latency by up to 82% for a micro benchmark and the Small Bank Benchmark [4].

2 BACKGROUND

We use the term optimistic concurrency control (OCC) to refer to the backward validation based OCC protocol introduced by Kung [33] in a loosely coupled architecture. As explained in the introduction, every transaction goes through three phases. First comes a *read* phase, where the transaction reads data from the storage and executes while making writes to a private "scratch workspace". Then the transaction enters a *validation* phase. If validation is successful, the transaction enters the *write* phase, when its writes are installed in the storage. The validator assigns each transaction a timestamp i, and it examines the transaction's *read set* $RS(i)$ and its *write set* $WS(i)$, and it compares them to the writes of previously committed transactions. When validating a transaction $T(j)$ with timestamp j, the validator needs to check for conflicts with all transactions $T(i)$ with timestamp $i < j$ that have already committed and that overlapped temporally with $T(j)$, i.e., $T(i)$ had not committed when $T(j)$ started. $T(j)$ can be serialized after such a transaction $T(i)$ if one of the following conditions holds:

- $T(i)$ completed its write phase before $T(j)$ started its write phase, and $WS(i) \cap RS(j) = \emptyset$, or
- $T(i)$ completed its read phase before $T(j)$ started its write phase, and $WS(i) \cap RS(j) = \emptyset$ and $WS(i) \cap WS(j) = \emptyset$

If $T(i)$ and $T(j)$ overlap temporally, and $WS(i) \cap RS(j) \neq \emptyset$, we say there is a *read-write dependency* from $T(j)$ to $T(i)$. Intuitively, if there is such a dependency, $T(j)$ cannot be serialized after $T(i)$. In addition, we must ensure the writes of the two transactions are installed in the correct order to maintain consistency in the storage. If they write to the same object, the updates must be applied in their serialization order. The original OCC algorithms achieve this by putting the validation and write phases in a critical section [33], but there has been much progress on OCC over the last decades that allows system designers to relax most of these assumptions. The above discussion implies that validation only needs to check, for every transaction $T(j)$ and all transactions $T(i)$ overlapping temporally with $T(j)$, where $i < j$, that $WS(i) \cap RS(j) = \emptyset$. Data versioning provides an easy way to determine whether $T(j)$ overlapped temporally with $T(i)$; every time a transaction performs a read, we tag the read with the version of the object that was read. If $T(j)$'s read set contains an object X and the read saw version k, the validator only needs to check the write sets of all $T(i)$ with $k < i < j$ to see whether they contain X [15]. For now, we assume the validation phase is sequential for ease of understanding. We will extend it to a parallelized design in Section 3.6. We handle out-of-order write requests with a *versioned* datastore, where every object in the datastore is versioned and every write request is tagged with a version number equal to the updating transaction's timestamp. If the datastore receives a write request with version (timestamp) i and a higher-numbered version $j > i$ already exists for the object, the write request is ignored.

3 BATCHING AND REORDERING

Batching involves buffering a number of operations as they arrive at some component of the system and processing them as a group.

Given a batch, we run a lightweight algorithm that analyzes the batch and then reorders the operations in the batch in order to reduce aborts. We will introduce two types of reordering opportunities: Storage batching and validator batching.

We first make a conceptual distinction between two types of transaction aborts: intra-batch and inter-batch aborts. Assume transaction T abort due to its conflict with T'. If T and T' are in the same batch, we call the resulting abort of T' an *intra-batch abort*; otherwise, we call it an *inter-batch abort*.

Batching transactions accessing the same objects together reduces inter-batch aborts. There has been a lot of research on data clustering either online or offline [16, 41], especially for fine-grained data partitioning.

In this work, we focus on managing intra-batch aborts by strategically reordering the batched requests at storage and validator. Reducing inter-batch aborts is complementary to our effort.

Our approach is agnostic to isolation levels as long as the reordering respects the corresponding definition of conflicts on the write-read, write-write, and read-write dependencies. In the following subsections, we describe how to batch and reorder for serializability. Our techniques can be adapted accordingly to other isolation levels, such as snapshot isolation.

3.1 Storage

If a transaction reads a stale version of the object at storage, it is bound to abort at the validator as it conflicts with the update from a committed transaction. Thus, applying updates at the storage layer as early as possible can reduce the chance of aborts for incoming transactions.

We buffer a number of read and write requests from transactions into batches. As a batch of requests comes, for each object, we apply the highest-version write request on that object. It is safe to discard all other writes on that object as explained in Section 2. Next, we handle all the read requests for the same object. This strategy is optimal for reducing intra-batch aborts, as it ensures that all available writes by committed transactions are applied to all objects before we handle any read requests on these objects.

3.2 Validator

In validator batching, we buffer transaction validation requests at the validator as they arrive. Once a batch is collected, the validator can reduce intra-batch aborts by choosing a good validation (and thus resulting serialization) order. Such intra-batch transaction reordering can be done with several goals in mind. We can simply minimize intra-batch aborts, i.e. we maximize the number of transactions in each batch that commit. Alternatively, we may also want to prioritize certain transactions to have a greater chance of committing. For example, if we want to reduce the transactions' tail latency, we can increase a transaction's priority every time it has to abort and restart. Priorities could also be related to external factors, e.g., a transaction's monetary value or an external, application-defined transaction priority.

3.3 Intra-Batch Validator Reordering (IBVR)

We now define the problem of *intra-batch validator reordering of transactions (IBVR)* more formally. A *batch* B is a set of transactions to be validated. We assume all transactions $t \in B$ are *viable*, that is, no $t \in B$ conflicts with a committed transaction. If there are non-viable transactions in B, they can be removed in preprocessing, as they must always abort. Given B, the goal of IBVR is to find a $B' \subseteq B$ of transactions that must abort due to intra-batch aborts. IBVR must also find a total order $\prec$ on $B \setminus B'$ that *respects all read-write dependencies*; that is, for $t, t' \in B \setminus B'$, if $t \prec t'$, then there is no read-write dependency from t' to t. The validator processes each batch by running IBVR to identify B' and $\prec$, aborting all the transactions in B' and validating the transaction in $B \setminus B'$ in the order $\prec$. By the constraint we gave on $\prec$ above, and from the discussion in Section 2, $\prec$ is guaranteed to be a valid serialization order that allows all transactions in $B \setminus B'$ to commit.

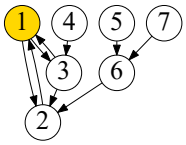

Figure 2: An example of a directed graph; node 1 forms a feedback vertex set.

There is always a trivial solution to any IBVR instance: aborting every transaction but one. Such solutions are not useful; therefore, every instance of IBVR is associated with an *objective function* on B', and the goal is to find a B' that maximizes the objective function. A simple objective function is the size of B' (smaller is better); a more complex one can take into account transaction priorities, etc. We call the objective function a *policy* P.

Every batch B of viable transactions induces a *dependency graph* G; this is a directed graph whose nodes are the transactions in B and whose edges are read-write dependencies.

If G is acyclic, then there exists a commit order Q on G that respects all read-write dependencies. We can construct Q by repeatedly committing a transaction whose corresponding node in G has no outgoing edge using topological sort. If G is not acyclic, we can show that the problem is NP-hard by reducing the NP-hard problem of finding a directed feedback vertex set to it [32].

A feedback vertex set (FVS) of a directed graph is a subset of vertices whose removal makes the graph acyclic. For example, consider the graph in Figure 2. The vertex 1 forms a FVS since the graph becomes acyclic after removing vertex 1 and its incoming and outgoing edges. Finding a minimal-size B' for IBVR is exactly the problem of finding the minimal (smallest-size) feedback vertex set on G. If we have a more complex objective function for IBVR, we can assign weights to the nodes to represent the desired transaction priorities, and look for a minimum-weight FVS. Once we find the FVS B', removing the nodes in B' from G yields an acyclic graph that determines the desired commit order Q.

The directed graph FVS (DFVS) problem is well-studied as it has many applications, including deadlock detection, program verification, and Bayesian inference. It is NP-hard and APX-hard [31, 32], and it is still an open problem whether there exists any constant-factor approximation. We propose two greedy algorithms for finding feedback vertex sets – one based on the graph's strongly connected components (SCCs) and the other based on sort. We also introduce a hybrid algorithm that makes strategic use of brute-force search; this is slower but more precise.

```
1  Algorithm GreedySccGraph(G, P)
       Input: Directed graph G, policy P
       Output: V, a feedback vertex set for G
2      V ← ∅
3      G' ← trim(G)
4      SCC = StronglyConnectedComponents(G')
5      for S ∈ SCC do
6          V ← V ∪ GreedyComponent(S, P)
7      end
8      return V
9  Algorithm GreedyComponent(S, P)
       Input: SCC S, policy P
       Output: V', a feedback vertex set for S
10     if S.size == 1 then
11         return ∅
12     end
13     v ← SelectVertexByPolicy(S, P)
14     S' ← GetGraphAfterVertexRemoval(S, v)
15     return v ∪ GreedySccGraph(S', P)
```

Algorithm 1: SCC-based greedy algorithm

```
1  Algorithm GreedySortGraph(G, P, k)
       Input: Directed graph G, policy P, multi factor k
       Output: V, a feedback vertex set for G
2      V ← ∅
3      G ← trim(G)
4      while G ≠ ∅ do
5          if G.size < k then
6              V ← V ∪ GreedySortGraph(G, P, 1)
7              break
8          end
9          Q ← QuickSelectVertexByPolicy(G, P, k)
10         for i = 1; i ≤ k; + + i do
11             V ← V ∪ Q[i]
12             G ← GetGraphAfterVertexRemoval(G, Q[i])
13         end
14         G ← trim(G)
15     end
16     return V
```

Algorithm 2: Sort-based greedy algorithm

3.4 Greedy Algorithms for IBVR

All our IBVR algorithms begin by constructing the dependency graph G. We start with a set of transactions that have been batched at the validator and construct B by discarding all non-viable transactions. We can identify such transactions by validating each transaction against all the updates prior to this batch. Next, we create one node per transaction, and one edge per read-write dependency. To determine whether a read-write dependency holds from transaction t' to t, we check whether $WS(t) \cap RS(t') \neq \emptyset$. If so, we add an edge from t' to t. This can be implemented by creating a hash table from the write sets and probing it with the read sets. Since a write in t can potentially conflict with all the other transactions in the batch, the time complexity to probe the hash table for a single write is $O(|B|)$, where $|B|$ is the size of the batch. The time complexity of building G is $O(|B|^2 + |R| + |W|)$, where $|R|$ is the total number of reads, and $|W|$ is the total number of writes.

We now process G to find a feedback vertex set. Both before and during the execution of our FVS algorithms, we *trim* the graph to remove all the nodes that have no incoming edges and/or no outgoing edges; such nodes cannot participate in any cycles and are thus extraneous for any FVS.

SCC-Based Greedy Algorithm. The intuition behind our first algorithm is that each cycle must be contained in a strongly connected component of the graph. After preprocessing, we partition the graph into SCCs. For a graph with V vertices and E edges, we can do this in time $O(|V| + |E|)$ using Tarjan's SCC algorithm [45].

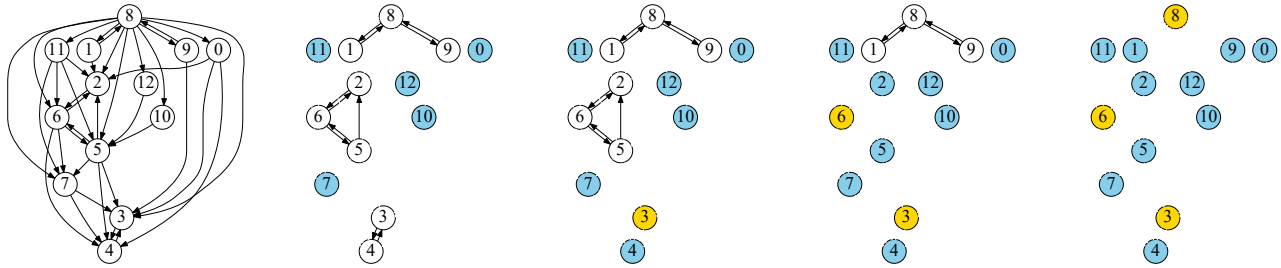
Nodes in SCCs of size one cannot belong to any cycle. For a SCC that contains more than one node, we choose a vertex to remove according to some *policy*. The policy is a ranking function over vertices, and we greedily choose the top-ranked vertex to remove. We then recurse on the remaining graph. Algorithm 1 shows the details of this procedure. We begin by trimming and partitioning the graph into SCCs (lines 3-4). We process each SCC S using $GreedyComponent(S, P)$ (lines 5-7). This subroutine starts by eliminating SCCs of size one (lines 10-12). Next, it chooses the top-ranked vertex v from S under Policy P (line 13). It removes v from S and recursively calls *GreedySccGraph* on the remaining graph S' (line 14 - 15). Finally, it returns the union of all the FVSs obtained in processing S (line 15). When the top-level procedure $GreedySccGraph(G, P)$ has processed all the SCCs of G, it returns the union of the FVSs obtained (line 8).

trim and updating the graph after removing a node takes $O(|V| + |E|)$ per graph in total, since each node / edge can be removed only once. In the worst case, e.g., in a fully connected graph, we may only remove one node per iteration. Since SCC takes $O(|V| + |E|)$ per iteration, the time complexity of this algorithm is $O(|V|(|V| + |E|))$.

The policy P is at the heart of the algorithm, and it affects both its accuracy and runtime. Fortunately, there is no trade-off between accuracy and running time; a more accurate policy will lead to a smaller FVS and faster termination. We discuss possible policies in Section 3.5.

Figure 3 shows the SCC-based greedy algorithm. The graph cannot be trimmed, so we partition it into SCCs. We remove all SCCs of size 1 – Nodes 0, 7, 10, 11, and 12 (Figure 3b). There are three remaining SCCs. We first look at the component containing Nodes 3 and 4. Since Nodes 3 and 4 have the same product of in-degree and out-degree, we can add either one of them to the FVS. We choose Node 3. Now Node 4 has neither incoming nor outgoing edges, so it is trimmed (Figure 3c). We repeat the process with the other components. For the SCC containing Nodes 2, 5, and 6, we add Node 6 to the FVS, as it has the largest product of in-degree and out-degree among the three nodes in this SCC. We now trim Nodes 2 and 5 (Figure 3d). Finally, we remove Node 8 from the last component, and trim Nodes 1 and 9 (Figure 3e). This leaves us with a final FVS consisting of Nodes 3, 6, and 8.

Sort-Based Greedy Algorithm. Our first algorithm relies on a SCC partitioning routine that takes linear time in the size of the graph. As this routine is called several times throughout the algorithm, it can cause a non-trivial overhead. Here we propose



(a) original (b) partition into SCCs (c) add 3 to FVS (d) add 6 to FVS (e) add 8 to FVS

Figure 3: An example of the SCC-based greedy algorithm using `prod-degree` policy

a faster greedy algorithm using a sort-based approach to remove nodes. Through extensive empirical tests of the SCC-based greedy algorithm we found that at each iteration, all the top ranked nodes in the graph are very likely to be included in the final FVS. Our second algorithm is based on this observation; it sorts the nodes according to their policy P, and includes the top-ranked k nodes in the FVS. We call k the *multi factor* of the algorithm. The algorithm removes these nodes and iterates on the remaining graph.

Algorithm 2 shows this in more detail. We start by trimming the graph (line 3); if the graph has no more than k nodes, we reduce the multi-factor to 1 (line 5-8). Otherwise, we sort and select top ranked k nodes into a queue Q using P with the Quickselect algorithm [29], and include the k nodes in V (line 9-13). After removing the selected nodes from G, we trim the remaining the graph again (line 14). We repeat this procedure until the graph is empty (line 4).

As with the previous algorithm, updating the graph after removing a node and *trim* takes $O(|V| + |E|)$ in total. The Quickselect algorithm [29] has an amortized time complexity of $O(|V|)$. In the worst case, it will take $O(|V|/k)$ iterations to terminate. So the overall time complexity is $O(|V|^2/k + |V| + |E|)$.

In practice, this algorithm is faster but less accurate than the SCC-based greedy algorithm. However, as we will see in Section 4, it produces results of comparable accuracy to the SCC-based algorithm in practice.

Figure 4 shows the same example using the sort-based greedy algorithm, with $k = 1$. After the first sort, we add Node 5 to the FVS since it has the highest product of in-degree and out-degree. After eliminating Node 5, Nodes 10 and 12 have only incoming edges, and get trimmed (Figure 4b). We sort the remaining nodes. This time, we add Node 8 to the FVS, and trim Nodes 0, 1, 9, 11 (Figure 4c). We repeat this process with the remaining nodes until the graph is empty. This yields a FVS consisting of Nodes 3, 5, 6, and 8 (Figure 4e), which contains one more vertex than the FVS we obtained with the SCC-based algorithm.

Hybrid Algorithm. We can combine the SCC-based greedy algorithm and the precise brute-force FVS search into a *hybrid algorithm*. The algorithm is similar to the SCC-based greedy algorithm but runs a precise, brute-force FVS search whenever it can afford to. Thus instead of processing all SCCs via the *GreedyComponent* subroutine (lines 5-7 of Algorithm 1), it runs the precise search when processing SCCs that are smaller than a certain *threshold*, and the greedy subroutine *GreedyComponent* on SCCs that are larger than the threshold. Adjusting the threshold allows us to trade off precision versus runtime.

3.5 Customizing Policies

Policies are of utmost importance for our algorithms. Recall that a policy is a ranking function on vertices of the graph, and a good policy ranks vertices which are likely to be in a desirable FVS highly.

We first discuss policies that aim at minimizing the number of conflicts, i.e., the size of the FVS. The simplest such policy is `random` that assigns all nodes random rankings. Alternatively, we can rank nodes using degree-based heuristics, which use the intuition that the removal of a node will break many cycles if the node is high in some measurement of its graph degree. Such heuristics have been shown to work well for FVS computation [13]. For example, the policy `max-degree` chooses the node with the largest degree (either in-degree or out-degree), `sum-degree` chooses the node with the largest total degree (in-degree plus out-degree), and `prod-degree` chooses the node with the largest product of in-degree and out-degree.

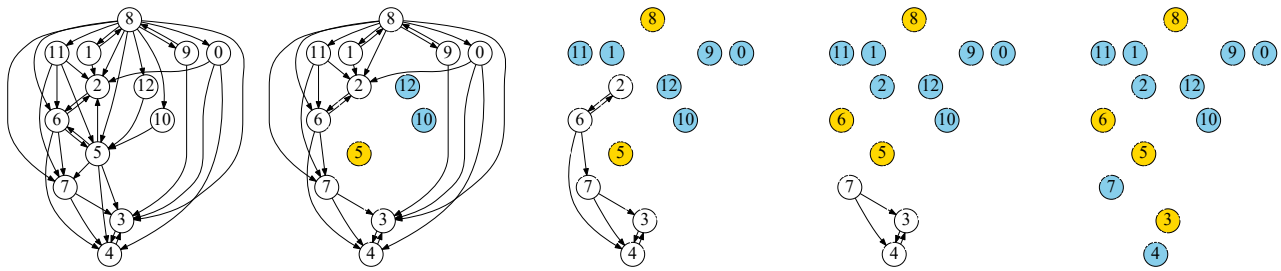
More sophisticated policies are possible if the system is optimizing a metric beyond maximizing the number of commits. For example, we may want to bound the transactions' *tail latency*; we can do that by incorporating latency information in our policies. We can rank transactions based on how many times they have been aborted and restarted; thus, transactions that have been restarted many times are less likely to enter the FVS and have a higher chance of committing. Alternatively, we can also devise policies that combine information about a transaction's number of restarts and its graph degree. For example, we can compute the ranking of a vertex as the product of its in-degree and out-degree divided by an exponential function of the number of restarts of the corresponding transaction.

In business applications, the monetary value of different transactions varies. Optimizing for *maximal monetary value*, we can design policies that favor more valuable transactions. For example, we can customize the policy to always add a transaction with the lowest value to the FVS until the resulting dependency graph is acyclic.

3.6 Parallel Reordering and Validation

Since reordering occurs online in transaction execution, it can increase the latency of a transaction, resulting in a higher chance of conflicts. We explain how parallelization can alleviate this problem by reducing the amortized overhead of reordering.

In centralized reordering, the validator prepares a batch of transactions, reorders them, validates them and caches the updates of transactions that commit. Each of these steps corresponds to a



(a) original (b) add 5 to FVS (c) add 8 to FVS (d) add 6 to FVS (e) add 3 to FVS

Figure 4: An example of the sort-based greedy algorithm using `prod-degree` policy and multi factor 1

subcomponent in the validator; we explain how we can parallelize execution across components through the use of pipelining, as well as within each component.

For pipelined parallelism, we can run each of the three validator subcomponents in a different thread. The batch preparation subcomponent receives requests from the processor, packages transaction into batches, and sends a reordering request to the transaction reordering subcomponent. Next, the transaction reordering subcomponent first pre-validates a batch of transactions based on the latest database snapshot available, then reorders the remaining transactions, and sends a validation request consisting of the remaining transactions to the transaction validation subcomponent. The transaction validation subcomponent takes a batch of ordered transactions, serializes them based on the order, validates them against updates from previously committed transactions, and applies the updates to the validator cache from transactions that pass validation.

In the single threaded centralized validator, a batch of transactions is pre-validated against the current snapshot of the database. Thus, the transactions that pass pre-validation can only conflict with transactions within the batch, and will not conflict with previous committed transactions. So after reordering, the remaining transactions all commit.

In the pipelined reordering, the validation is decoupled into two phases. We denote a database snapshot as S_k, where transactions whose timestamps are less or equal to k have been committed as of this snapshot. In the reordering subcomponent, a batch of transactions B is validated against the latest database snapshot S_m. The remaining transactions after pre-filtering are reordered as a batch B' and sent to the validation. B' is again validated against the current database snapshot S_n. Since the validation subcomponent can be validating uncommitted transactions while B is being processed at the reordering subcomponent, when B' arrives at the validation, we may have $n \geq m$. Thus, transactions in B' can still abort due to conflicts with previously committed transactions in S_n.

We can further introduce parallelism into each of the subcomponents. In batch preparation, multiple threads can package transactions into batches. We can either assign each processor to send its validation request to a specific batch preparation thread, or we can create a consumer-producer queue to connect the processors and the batch preparation threads. In transaction reordering, multiple threads can consume reordering requests from the batch preparation threads, and reorder batches of transactions concurrently. Since the transactions are not serialized yet in the reordering stage, the

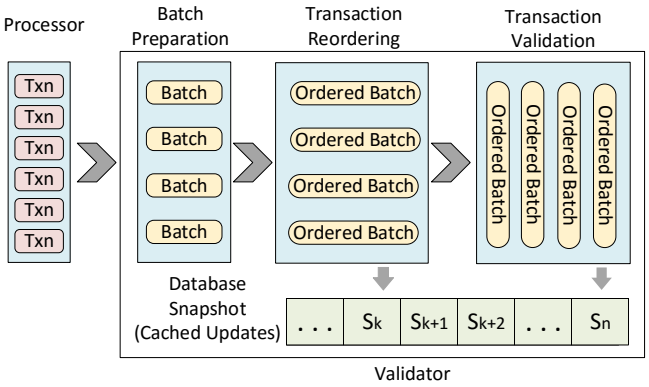


Figure 5: The architecture of parallel validator. It is decoupled into three subcomponents for pipeline parallelism: batch preparation, transaction reordering, and transaction validation. Each subcomponent can be further parallelized.

threads can send the processed batches to the validation subcomponent in any order. At the validation subcomponent, transactions are serialized and validated against all previously committed transactions. We cannot simply validate each individual transaction on a different thread since transactions come from different batches can conflict with each other. However, within an ordered batch, since the only source of conflicts is from all the transactions committed prior the batch, the validation of each transaction within a batch can be processed in parallel. Since conflicts can happen across batch boundaries, processing a new batch should only start after all the transactions are processed in the previous batch. Within a batch, the transactions are serialized by the ordering produced from the reorder subcomponent. The updates from committed transactions in a batch are applied to the validator cache at the end of the processing of the batch.

Figure 5 shows the architecture of our parallel validator.

Alternatively, the transaction validation can use partitioned parallelism. The idea is to partition the key space and break a transaction into smaller pieces, and one thread is assigned to validate transaction pieces on one partition. More discussion on this design can be found in our previous Centiman system [15].

4 EVALUATION

In our evaluation, we wanted to understand the effect of batching and reordering, the performance of our validator reordering algorithms and policies, and the impact of parallelization at validator

as well as configuration parameters. In particular, we asked the following questions:

(1) How well do our validator reordering algorithms from Section 3.3 perform? How does batching and reordering at validator using these algorithms affect the end-to-end system performance?
(2) What's the impact of batch size on performance?
(3) How does parallel reordering affect performance?
(4) How does storage and validator batching and reordering affect system performance?
(5) How well do the different policies from Section 3.5 work?
(6) How does batching and reordering perform on real workloads?
(7) How well do our techniques adapt to data contention comparing to other systems?

4.1 Implementation and Experimental Setup

Our system architecture has four components: transaction generator, processor, storage, and validator. The components communicate through consumer-producer queues.

The transaction generator continuously produces new transactions until the system reaches the maximum permitted concurrency level. The processor multiplexes transactions as a transaction coordinator, receives transaction requests from the transaction generator, sends read/write requests to the storage, sends validation requests to the validator, and replies to the transaction generator. It also restarts aborted transactions; thus, it only communicates commit decisions to the transaction generator. The storage continuously processes read and write requests. When storage batching is enabled, it buffers requests into batches, and uses the optimal strategy described in Section 3: It first executes all the write requests in the batch and then all the read requests.

The validator performs backward validation. For every transaction, a validation request consists of the keys and versions of its reads and the keys of its writes. The validator caches the write keys of committed transactions in an in-memory hash table, until these writes are overwritten by later updates. When batching is enabled, the validator collects the requests into a batch as they arrive, and runs one of the algorithms from Section **??** to determine a serialization order. Every transaction that passes the validation is assigned an integer *commit timestamp*, which corresponds to the version number of the updates it will install in storage.

We have further decoupled the validator component into three subcomponents as described in Section 3.6. A batch preparation worker receives validation requests from the processor, packages transactions into batches, and sends them to transaction reordering workers. A transaction reordering worker pre-validates and filters the transactions in a batch against the validator cache, reorders the transactions, and sends the batch of ordered transactions to the validation workers. A validation worker validates transactions against the current validator cache, and applies updates from committed transactions to the cache based on the transaction serialization order.

By default, the validator uses the sort-based greedy algorithm with the `prod-degree` policy and multi factor 2. To process a batch, we create a dependency graph as described in Section 3.3. We have empirically determined that validator reordering is not beneficial if the dependency graph is very dense, as there are fewer opportunities for conflict reduction. Therefore, we heuristically set a limit on the size of the dependency graph. Once we detect that the number of edges has hit this limit during the construction of the dependency graph, we discard the graph and validate the transactions without reordering.

We have parallelized the transaction generation, the storage, and the transaction reordering at the validator. By default, two transaction generators populate the transactions concurrently to supply sufficient load. Two storage workers concurrently process reads and writes, and the writes are applied based on its data versioning as described in Section 3. In the validator, we first introduced pipeline parallelism by processing the three subcomponents concurrently. Since we observed that transaction reordering is heavier weight as compared to the other subcomponents, we increased its capacity by multi-threading. We used four transaction reordering workers by default.

Our system is implemented in Java. All the experiments run on a machine with Intel Xeon E5-2630 CPU @2.20GHz and 16GB RAM. We use a key-value model for the storage, implemented as an in-memory hash table. In our micro benchmark, we populate the database with 100K objects, each with an 8-byte key. The values are left null as they are not relevant to our evaluation. We generate a transactional workload where each transaction reads 5 objects and writes to 5 objects drawn from a Zipfian distribution [24], with one of the reads and one of the writes on the same object. We limit the concurrency level to 300, i.e., at any time there are at most 300 live transactions in the system. The default batch size is 40 for both storage and validator.

The baseline configuration (*baseline*) represents the system running with both storage and validator batching turned off. We optimize the code path for transactions without batching to avoid the overhead from batching and reordering, including skipping packing transactions into batches as well as the reordering workers in validator. We further add a batch mode (*batch*) to separate the effect of batching and reordering, where requests are batched at both storage and validator, but no reordering is performed. The batch mode can benefit from better caching with tighter loops in the processing.

All our experimental figures show the averages of 10 runs, each lasting for 60 seconds in between a 10-second warm-up and a 10-second cool-down time. The standard deviation was not significant in any of the experiments, so we omit the error bars for clarity of presentation. We report the good throughput (the number committed transactions per second), the average latency, and the percentile latency.

4.2 Validator Reordering Algorithms

We first investigate the performance of the feedback vertex set algorithms from Section 3.3 with a comparison of the raw performance of the algorithms, i.e., their accuracy and running time. We run the algorithms on graphs constructed as described in Section 3.3, using our micro benchmarks.

We test the SCC-based greedy algorithm with the `max-degree` (*greedy_max*), `sum-degree` (*greedy_sum*) and `prod-degree` policies (*greedy_prod*). We also test the sort-based greedy algorithm

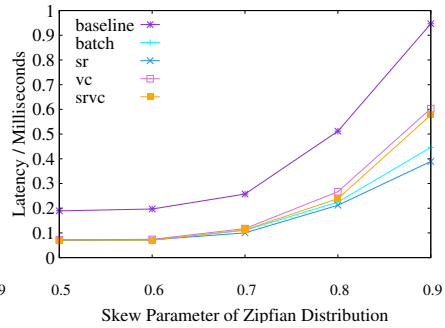

Figure 25: Average latency with Small Bank benchmark

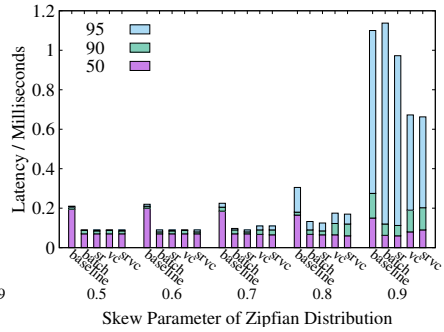

Figure 26: Percentile latency with Small Bank benchmark

is larger than m, and switches to the brute force search otherwise. By increasing the threshold, we can progressively approximate the optimal solution.

We test these algorithms against several baselines: *search* is an accurate, brute force search algorithm; *random* is the SCC-based greedy algorithm which removes a vertex at random from each SCC to break the cycle. For each graph, *random*_3 runs *random* 3 times and returns the smallest FVS, mitigating the effect of bad random choices.

Figure 6 shows the average size of the feedback vertex set found by each algorithm. The brute force search algorithm is so slow that it cannot produce results once the skew factor increases beyond 0.7 as the graphs become denser. The *random* baseline computes a FVS whose size is almost twice as large as the greedy and the hybrid algorithms. Running the random algorithm multiple times produces similar results. This confirms the theoretical results which show that finding a good FVS is hard. The greedy algorithms, on the other hand, produce very accurate results. The average size of the FVS is almost identical to that of the brute force search when the skew factor is no larger than 0.7, and is very close to the best hybrid algorithm (*hybrid*_20, i.e., one that uses the brute force search when the size of the SCC is no larger than 20). Among the greedy algorithms, *greedy_prod* is consistently the best, although the difference is small.

Figure 7 shows the running time of the algorithms. The running time of the hybrid algorithm depends on the threshold for switching to brute force search. Thus, *hybrid*_20 and *hybrid*_15 have a longer running time than other algorithms, while the running time

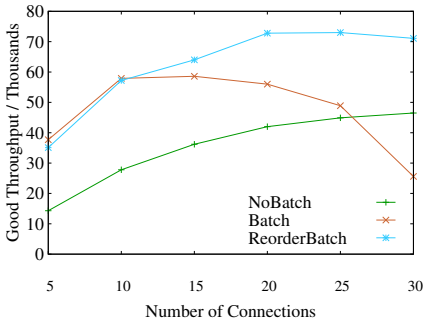

Figure 27: Good throughput of DBMS-X with SmallBank benchmark

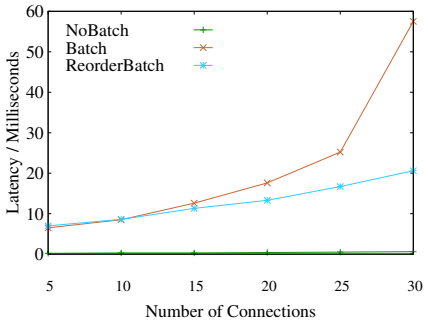

Figure 28: Average latency of DBMS-X with SmallBank benchmark

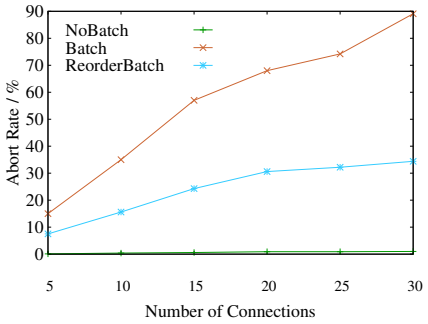

Figure 29: Abort rate of DBMS-X with SmallBank benchmark

of *hybrid*_10 is comparable to the SCC-based algorithms. Each of the SCC-based algorithms (*greedy_max*, *greedy_sum*, *greedy_prod*, *random*) has a similar running time. The random algorithm takes slightly longer than the greedy algorithms because it removes more nodes and thus requires more computation. The running time of *random*_3 is three times that of *random*, since it runs the random algorithm three times. The sort-based greedy algorithm (*greedy_sort*), while slightly less accurate than the SCC-based greedy algorithms, reduces the running time of these algorithms by 74%.

We compare the end-to-end performance of the best SCC-based algorithm (*greedy_prod*) against the sort-based greedy algorithm. Figure 8 and 9 show the throughput and the average latency of the system with *greedy_prod* (*srvc-g*) and *greedy_sort* (*srvc-gs*). In both cases, storage batching is enabled. The *baseline* line shows the throughput with both storage and validator batching disabled.

The two greedy algorithms have similar throughput when the skew is very low. However, *greedy_prod* degrades significantly when data skew increases. This is because while *greedy_prod* is slightly more accurate, it takes much longer to run. This increases transaction latency and leads to more conflicts, especially when the data contention is high. *greedy_sort* consistently gives the highest throughput over all the workloads for its high accuracy and low running time.

Figure 10 shows transaction latency by percentile, i.e., the latency threshold for up to 95% of the transactions. The tail latency of *greedy_sort* is much lower than that of the other two, which is consistent with the throughput data.

4.3 Parallel Validator Reordering

In this experiment, we study the benefit of introducing parallelism into validator. Since we have observed that the reordering of the FVS is the most time consuming subcomponent in the validator, we increase the number of threads to parallelize batch reordering as described in Section 3.6.

Figure 11 and 12 show the throughput and the average latency with the number of reordering workers from 1 to 4 (*rw*-1, *rw*-2, *rw*-3, *rw*-4). The performance improves significantly with more reordering workers when the skew factor is medium to high. With 4 reordering workers, the throughput is increased to up to 2.6x, and the average latency is reduced by up to 39%, as compared to with 1 reordering workers. Figure 13 shows the percentile transaction latency. With more reordering workers, more transactions are reordered concurrently, and the transaction queuing time at validator has reduced. With 4 reordering workers, the tail latency has reduced by up to 41% as compared to with 1 reordering workers.

Yet we didn't expect linear performance improvement since the bottleneck of the system may shift to other components as we increase the capacity of the transaction reordering. The system can further scale up once the capacity of other components is carefully engineered and scaled, which is out of scope for this paper.

4.4 Batch Size

In this experiment, we explore the impact of batch size on system performance. Smaller batch sizes should give lower latency but they offer fewer opportunities for reordering, leading to more aborts. We configure the system to perform both storage and validator batching with batch sizes from 40 to 240. Figure 14 and 15 shows the throughput and average latency with different batch sizes as data skew increases. The throughput first rises as we increase the size of the batch, and then degrades when the batch becomes too large. Batch size 40 gives the best throughput and the latency. The percentile latency displays a similar pattern, as shown in Figure 16.

4.5 Storage and Validator Batching

Next, we perform a detailed analysis on the effects of storage and validator batching. We configure the system in several different modes: no batching (*baseline*), batching without reordering (*batch*), storage batching only (*sr*), validator batching only(*vc*), and both storage and validator batching (*srvc*).

Figure 17, 18, and 19 show the throughput, the average latency, and the percentile latency of different system modes under a variety of data skew parameters.

Overall, using batching at storage and/or validator consistently leads to significant improvements in throughput to up to 2.7x. In addition, storage and validator reordering consistently further improve the throughput to up to 1.3x as compared to *batch*. Moreover, validator reordering significantly reduces the average latency, by up to 67%, and the percentile latencies, by up to 82%, as compared to *baseline*, and by up to 25% and 70% as compared to *batch*.

When the data contention is extremely high, the number of intra-batch conflicts that cannot be resolved by validator reordering increases. Validator reordering is slower due to denser graphs, while bringing less benefit. Thus, the best throughput is achieved by using storage batching only (*sr*).

We conducted additional experiments with the batch size fixed to evaluate the system's peak performance with the load varied. Figure 20 shows the throughput of the system with batch size 20 and skew factor 0.7. Enabling both storage and validator batching consistently outperforms the others. The throughput increases to up to 2.5x, and the average latency reduces by up to 63% as compared to *baseline*. The figures on additional metrics and parameters are omitted due to the space limit.

4.6 Reduce Tail Latency

We explore validator reordering with a more complicated policy presented in Section 3.5; specifically, we look at policies that aim to reduce the transaction tail latency.

We explore the possibility of reducing transaction tail latency with latency-specific policies. Our baselines are the `prod-degree` policy that maximizes the number of commits (*max-c*) as well as *baseline* and *batch*. Our first tail-latency aware policy (*rst-cnt*) favors transactions that have already been aborted and restarted. When choosing a node to include in the FVS, it chooses the one with the smallest number of restarts, breaking ties using `prod-degree`. The second latency-aware policy considers both the number of restarts and a degree-based measurement of a transaction. It computes the weight of a node as the product of in-degree and out-degree over the exponential of the number of restarts with base 2. When choosing a node to include in the FVS, it picks the node with the highest weight. Thus, a node with a high degree product can have its weight reduced if the corresponding transaction has restarted many times.

Figure 21 and 22 show the throughput and the average latency. The impact of tail-latency aware policies on transaction throughput and average latency are negligible as compared to when we maximize the number of commits (*max-c*). Figure 23 shows the tail latency from 90% to 100%, i.e., the latency threshold for from up to 90% to up to 100% of the transactions. While our first latency-aware policy *rst-cnt* performs similar to *max-c*, the more sophisticated policy *rst-cnt* consistently performs significantly better than all the others, and reduces the tail latency by up to 86% as compared to other policies.

4.7 Small Bank Benchmarks

The Small Bank benchmark contains transactions with a realistic and diverse combination of read and write conflicts. The transactions come from the financial domain: compute the balance of a customer's checking and savings accounts, deposit money to a checking account, transfer money from a checking account to a savings account, move funds from one customer to another, and withdraw money from a customer's account. We use a Zipfian distribution to simulate skewed data accesses. We populate the database with 100K customers, i.e., 100K checking and 100K savings accounts.

Figure 24, 25, 26 show the throughput, the average latency, and the percentile latency of transactions. Overall, batching and reordering has improved the throughput up to 3.1x, while reduced by up to 68% for the average latency, by up to 62% for the tail latency, comparing to *baseline*. Storage and validator reordering always improve the throughput and reduce the latency on top of batching, confirming our findings in Section 4.5.

4.8 Implementation on DBMS-X

In our final experiment, we implemented the idea of transaction batching and reordering on the client side of a commercial DBMS-X. DBMS-X is a high performance OLTP engine using optimistic concurrency control. Upon receiving transactions, it processes transactions concurrently with a first-come-first-server order. We implement transaction batching and reordering at the client side of DBMS-X as a proof-of-concept.

In many applications and services, clients submit transactions to databases via a middle-layer, such as a web server. This web server consolidates requests from potentially a large number of clients, processes the requests, reroutes the requests to different database servers, and responds to the clients. The web server often batches transactions from different clients to improve throughput and resource efficiency.

As a prototype, we implemented validator reordering for the transactions batched at the web server. Since the transactions haven't started executing and their read timestamps are not available, we conservatively assume all the transactions in the batch read from the same snapshot of the database. We analyze the potential conflicts between the transactions, and then we maximize the number of commits of transactions with our reordering algorithm, using a policy considering both how many dependencies a transaction involves and how long it has been waiting. For the transactions excluded from the batch, they will be included in the next batch for reordering, together with future incoming transactions.

We use SmallBank benchmark of Zipfian skew 0.9 as a highly contended scenario. We compare transaction batching and reordering (*BatchReorder*) with two other baselines: no batching (*NoBatch*) and batch without reordering (*Batch*). In *NoBatch*, we transactions to DBMS-X one at a time. In *Batch* and *BatchReorder*, we batch the transactions before sending the transactions to DBMS-X. We choose a batch size of 50, which is a throughput-wise reasonable batch size for this workload.

Figure 27, 29, and 28 show the throughput, latency, and abort rate when we increase the number of database connections. When we do not batch the transactions, the number of concurrent transactions is small and the throughput is low. As a result of low concurrency level, the chance of conflicting is small. Thus, both abort rate and latency are low. As we send transactions in batches, the throughput increases dramatically. However, as the load continues to increase, the system runs into data contention, which leads to resource contention due to restarts. The abort rate and latency rise significantly. When we both batch and reorder the transactions, the performance improves in all metrics: higher peak throughput by 1.25x, higher throughput by up to 3.1x, lower latency by up to 66%, and abort rate by up to 62%. In addition, the system performance degrades much more gracefully when the system load continues to increase.

4.9 Experiment Summary

We now summarize the results of our evaluation:

(1) The simple sort-based FVS greedy algorithm is highly accurate, and reduces the running time of the SCC-based greedy algorithms by 74%, leading to the best overall system performance.
(2) There is a sweet spot for the batch size, where the system achieves its best combination of throughput and latency. We

empirically selected the best batch size for our configuration and workload based on the results.

(3) As we increase the level of parallelism in validator reordering, the throughput, latency, and percentile latency all improve, especially when the data contention is medium to high.

(4) Batching and reordering increase the throughput by up to 2.7x, and reduce the average and the percentile latency by up to 67% and 82% respectively, as compared to the baseline. Batching by itself improves throughput significantly. Adding reordering on top of batching consistently improves throughput by up to 1.3x, and significantly reduces the average and the percentile latency by up to 25% and 70% respectively. It is always beneficial to use storage reordering. Validator reordering consistently improves the tail latency but can hurt the throughput and latency when the data contention is at the extremes.

(5) For alternative reordering policies at the validator, privileging transactions with a combination of the degree of the transaction in the dependency graph and its restart time significantly reduces the tail latency by up to 82% as compared to other policies, without sacrificing the throughput nor the latency.

(6) In Small Bank benchmark, batching and reordering improve the throughput by up to 3.1x and reduces the average and percentile latency by up to 68% and 62% as compared to the baseline.

(7) Finally, we implement the transaction reordering idea on the client side of a commercial database system DBMS-X. Our experiment on Small Bank benchmark shows that, under high data contention, our technique increases the throughput by up to 2.8x and reduces the average latency by up to 66%.

5 RELATED WORK

We discussed OCC and its applications in Sections 1. Here, we discuss related work on concurrency control under high data contention, transaction scheduling, and batching.

High contention concurrency control. The performance of concurrency control protocols suffers when concurrency level and data contention are high [20]; this has particular impacts on OCC [3]. Hybrid approaches combine OCC and locking to limit the number of transaction restarts [46, 52]. The problem can also be addressed by adjusting the concurrency level adaptively [28]. Transaction chopping reduces contention by partitioning transactions into smaller pieces and executing dependent pieces in a chained manner [38, 44, 51]. Follow-up work explores other ways to analysis transaction access patterns and expose intermediate transaction state at fine-grained as well [49]. It is also possible to reduce conflicts by executing transactions at heterogeneous isolation levels [50, 51] or using a mix of optimistic and pessimistic concurrency control protocols [48]. While we also address the problem of reducing conflicts under data contention, our batching and reordering techniques are different from and complementary to previous work.

Transaction scheduling. The dynamic timestamp assignment technique assigns each transaction a timestamp interval and flexibly picks the commit timestamp from the interval [6]. A similar technique can be used to optimize read-only transactions in distributed asynchronous OCC [15]. This approach can be extended to dynamically update the timestamp intervals of live transactions while committing a different transaction [10]. Dynamic timestamp assignment is compatible with our batching.

Transaction scheduling has also been studied in real-time databases, where urgent or high value transactions are prioritized [27]. OCC with forward validation enables the validator to choose what to abort or defer a transaction if it would cause live transactions with higher priority to abort [26, 34, 36]. There are also systems that use locking and preemption [1], as well as hybrid optimistic/pessimistic methods [30, 37]. These approaches can be viewed as a simplified version of our validator reordering; moreover, none of the systems uses batching. Transactions can be batched and serialized before execution [18, 38, 47]. These are complementary to our work. Our approach is more flexible as it allows reordering at multiple stages in transaction execution.

Batching. Batching to amortize costs and condense work is a common optimization technique. One application is to pack networking and logging messages [11, 15, 22, 23]. Batching is also widely applied to application requests to improve performance, including group commits [14, 25], condensing IO requests [14, 19], and Paxos [43]. Since batching is often associated with a throughput/latency tradeoff, there is work on adaptive batching [21, 39]. Those uses of batching are low-level and are not aware of the overall system infrastructure or the application semantics. Our work embraces batching as a core design principle at multiple stages of transaction execution. In addition, unlike previous work, we focus on the use of batching for reordering.

6 CONCLUSIONS AND FUTURE WORK

We have shown how to improve transaction performance in an OCC system by integrating batching and reordering into the system architecture at storage and validator. Batching allows the reordering of requests and reduces the number of aborts. We have formulated validator reordering as the problem of finding the minimal feedback vertex set (FVS) in a directed graph, and we have proposed two greedy algorithms for finding a FVS that are flexible and that perform well in practice. We have carried out an extensive experimental study in a main memory transaction processing prototype, as well as implemented a client side solution for a commercial database. Our experiments show that there is a sweet spot for the batch size for the best balance between latency and the flexibility of reordering. We have also investigated the impact of storage and validator batching on system performance. While both storage and validator batching consistently improve the throughput, validator reordering significantly reduces the latency profiles. We further proposed a parallel validator design. Our experiments showed that parallel reordering has improved both throughput and latency.

In future work, we plan to explore more sophisticated batch creation techniques, as well as systematically investigating adaptive batching to intelligently enable batching and adjust batch sizes for best system performance. As recent open source transaction processing kernels offer impressive read / write throughput, we also want to explore the opportunity to incorporate our techniques into these kernels.
